

Prevalence of Actinic Keratosis in Different Regions of Spain: The EPIQA Study

Prevalencia de la queratosis actínica en diferentes regiones españolas: estudio EPIQA

Dear Editor:

Actinic keratoses (AKs) are common cutaneous lesions that develop as a result of ultraviolet (UV) radiation damage.¹ Risk factors associated with AKs include advanced age, male gender, high degree of sun and/or artificial UV exposure, and fair skin.² Epidemiological studies within Europe are limited and have provided highly variable estimates of AK point prevalence (1–38%).^{2–6} Cumulative sun exposure, demographic AK risk factors, and lifestyle characteristics have likely contributed to the wide-ranging estimate of European AK prevalence.^{7,8}

Comprehensive studies that measure nationwide AK prevalence within Europe would provide essential information that would aid the development of pragmatic AK management guidelines. The aim of the EPIQA study was to assess the prevalence of AKs among dermatology outpatient clinics in Spain.⁹ In this analysis, we report the secondary objective of describing dermatology outpatient clinic AK prevalence within four regions of Spain with different climate conditions.

The EPIQA study was an observational, cross-sectional, multicentre study that included patients attending general dermatology outpatient clinics in Spain.⁹ In order to

represent the entire country, clinics were selected and divided into four geographical regions based on climatic conditions and lifestyle: Northern (Galicia, Asturias, Navarra and Aragón), Central (Castilla-León, Madrid, and Castilla-La-Mancha), Mediterranean (Cataluña, Comunidad Valenciana and Murcia) and Southern (Extremadura and Andalucía) regions. Whole-body examinations were performed by certified dermatologists who visually confirmed AKs. Medical history, profession, and sun/UV exposure habits were collected via standardised interviews. Statistical analysis have been previously described.⁹

A total of 3877 patients were included with characteristics shown in Table 1. Overall, age and sex were similar between regions. Age distributions were also similar between regions, with ages 45–50 representing 11.9% and >80 years old representing 14.0% of the population. Actinic keratosis being the reason for the dermatology consultation varied from 15.9% to 23.3%. Most patients reported low occupational but moderate recreational sun exposure.

In the study population, 1110 presented with AKs (28.6%, 95% CI: 27.2, 30.1). AK point prevalence (95% CI) differed significantly between regions, with 31.4% (29.1, 33.7) in the Mediterranean, 28.1% (24.5, 31.7) in the South, 27.5% (24.4, 30.6) in the North and 24.9% (22.0, 27.8) in the Central region ($p=0.006$). The most significant difference in prevalence was observed between Central and Mediterranean regions ($p<0.05$). Communities with the highest AK point prevalence were located in the Northern (Aragón, 39.6%), Mediterranean (Cataluña, 40.1%), and Southern (Extremadura, 36.6%) regions. Point prevalence was highest in men aged ≥ 51 years old ($p<0.001$) (Fig. 1).

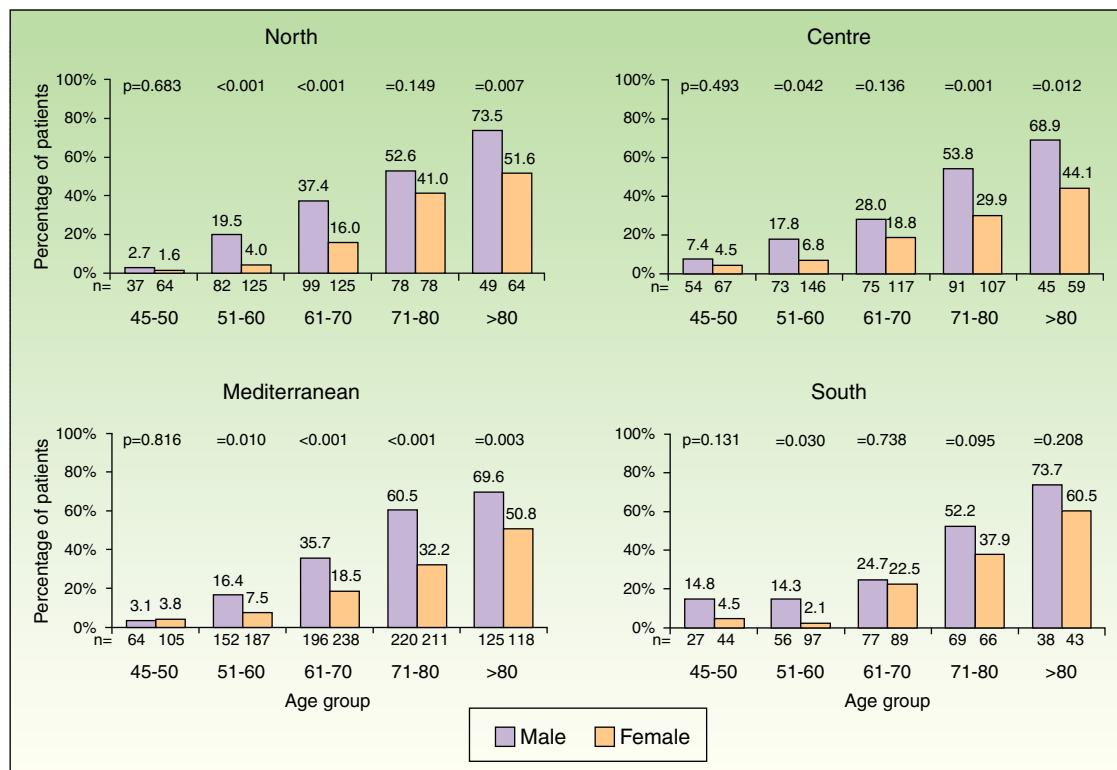

Figure 1 Prevalence of AKs according to age and sex.

Construction, craft and related trades	63 (7.8)	76 (9.0)	243 (15.0)	49 (8.1)

^a Low: none; moderate: under 2 h outside; high: all day outside.

^b Low: none; moderate: irregular outdoor activity participation; high: regular participation in outdoor activities all year round.

^c Occupations listed which include ≥10% total sample population.

A comparison of patients diagnosed with AK found a significant difference between regional skin phototypes and no difference between regional history of non-melanoma skin cancer (Table 2). In all regions, the most prevalent phototypes were types II and III, which cumulatively accounted for 80–90% of all AK patients. A significantly higher proportion of AK patients in all regions reported that AKs were the reason for consultation, compared to other reasons ($p=0.006$). Significant regional differences were observed when related to occupational ($p<0.001$), but not to recreational ($p=0.267$), sun exposure (Table 2).

The distribution of anatomical areas with AK lesions was similar between regions and, in general, significantly more frequently reported on the face for women and the scalp and ears for men (Supplementary Table 1). A comparison of the number of lesions by location showed no regional differences (Supplementary Table 2).

Overall, there were observed regional differences in skin phototype, the reason for consultation, and occupational sun exposure. While skin phototype and occupational sun

exposure were anticipated to differ due to regional demographic and employment variability, significant differences in the percentage of patients seeking a consultation for AK suggests differing regional attitudes towards seeking healthcare services or healthcare availability. Furthermore, as 30–42% of patients with AKs ignored these lesions, it is clear that AK remains an underdiagnosed condition within Spain.

In agreement with previous results, lesion location was consistent between regions; more frequent on the scalp and ears for men, and the face for women.¹⁰ Furthermore, despite regional variation in AK risk factor frequency, no significant differences in the number of lesions were observed.

Some limitations of this study include the unequal recruitment from each autonomous community that may have imbalanced regional comparisons and the restriction of the study population to patients visiting dermatology clinics. However, to the best of our knowledge, this is the first study that has investigated regional variation of AK prevalence within a single European country.

In summary, significant regional differences in AK prevalence have been observed in Spain; predominantly related

Table 2 Lifestyle and clinical characteristics of AK patients.

to sex and age. Regional differences in skin phototype and occupational sun exposure do not appear to influence lesion location or severity. It is striking that despite regional differences, a high proportion of patients in Spain did not seek advice regarding their AKs. These findings highlight that regional variation in AK prevalence exists and are of value to national AK screening and management initiatives.

Conflict of interest

Morfea y liquen escleroatrófico extragenital generalizados tras vacuna antígrupal

Morphea and Exogenous Lichen Sclerosus et Atrophicus After Influenza Vaccination

Sra. Directora:

Morfea y liquen escleroatrófico (LEA) son 2 enfermedades cutáneas crónicas de etiopatogenia desconocida, en las que se ha postulado la relación con factores genéticos, autoinmunes e infecciosos. Son pocos los casos descritos tras la administración de vacunas.

Una mujer de 67 años, con antecedente de cáncer de mama tratado mediante mastectomía radical e implantación de prótesis de silicona 15 años antes, es remitida a nuestro servicio por prurito y endurecimiento progresivo de la piel. No había recibido radioterapia complementaria a la mastectomía ni tomaba fármacos de interés. Refería el inicio de los síntomas a los 10 días de haber recibido en el deltoides izquierdo la primera dosis intramuscular de 0,5 ml de

Chiroflu®, vacuna antígrupal de antígeno de superficie inactivado. Inicialmente la lesión se localizaba en el deltoides izquierdo, lugar de la inyección de la vacuna. Gradualmente fueron extendiéndose las lesiones hasta generalizarse, respetando únicamente la cara y provocando dificultad para la movilidad, en especial de los hombros y las rodillas. La exploración física mostraba en algunas zonas grandes placas blanco-nacaradas e induradas (fig. 1) y, en otras, la piel tenía aspecto atrófico y arrugado (fig. 2). Los estudios de laboratorio, incluyendo hemograma, bioquímica, anticuerpos antinucleares, anti-scl 70 y anti-centrómero y serología de Borrelia burgdorferi fueron normales o negativos. La biopsia de piel mostró una epidermis atrófica con oclusión folicular y degeneración de la capa basal, edema en la dermis papilar, colágeno de aspecto hialinizado y un infiltrado linfocitario en banda. En la misma muestra también se encontraba una dermis reticular engrosada con haces de colágeno gruesos y compactos y un infiltrado inflamatorio crónico (fig. 3). Con estos hallazgos clínicos e histopatológicos se diagnosticó a la paciente de morfea y LEA extragenital generalizado y se inició tratamiento con PUVA oral. Dada la escasa respuesta después de 48 sesiones de tratamiento, se pautó prednisona oral 20 mg/día en combinación con metotrexato subcutáneo
