Interferon Eyedrops in the Treatment of Basal Cell Carcinoma of the Eyelid

Colirio de interferón y carcinoma basocelular palpebral

To the Editor:

Interferons (IFN) are a family of pleiotropic cytokines that exert antiviral and antitumor effects through several different mechanisms (Table 1). These cytokines are of interest to dermatologists mainly because of their effectiveness in the treatment of basal cell carcinoma (BCC), squamous cell carcinoma, Kaposi sarcoma, and melanoma.

Intralesional IFN was first demonstrated to effectively treat BCC in 1986, and it produced complete responses in between 67% and 80% of patients in published series. IFN can be administered as monotherapy or as an adjuvant after surgery. Here, we describe the use of IFN administered topically in ophthalmic eyedrops in the management of a BCC on the free margin of the eyelid. This formulation is used in ophthalmology to treat squamous conjunctival papillomata, squamous neoplasms of the ocular surface, Kaposi sarcomas, and conjunctival melanomas.

We report the case of an 88-year-old woman with a histologically-confirmed, solid papular BCC of 5 mm in diameter on the margin of the lower left eyelid (Fig. 1). The patient refused surgical treatment. Other treatment options, such as photodynamic therapy and imiquimod cream, were considered, but were ruled out due to the characteristics and location of the lesion. The patient also refused treatment with intralesional IFN due to a fear of injections. It was decided to treat the BCC with IFN alfa-2b in ophthalmic eyedrops at a concentration of 1 million IU/mL, administered 4 times per day. This treatment was continued for 4 months, resulting in a decrease in the size of the lesion (Fig. 2). No adverse effects were observed during treatment, and there was no change in the clinical appearance of the lesion on follow-up at 39 months. The patient still refuses to undergo either surgery or a control biopsy.

The efficacy of IFN alfa-2b eyedrops in various tumors of the conjunctiva, eyelid, and ocular surface is described in the ophthalmic literature. The recommended dose is 1 drop of IFN alfa-2b at 1 million IU/mL 4 times per day for 3 to 4 months. Some authors recommend a maintenance regimen of 1 drop every 12 hours. Several studies have compared ophthalmic with intralesional IFN alfa-2b administration in the treatment of both non-invasive and invasive ocular surface squamous neoplasia, reporting better patient compliance and lower rates of local and systemic side effects in patients treated with eyedrops. The only local side effects reported are mild and resolve upon discontinuation of treatment. They include punctate keratitis, follicular conjunctivitis, and conjunctival hyperemia. Development of the flu syndrome characteristic of systemic or intralesional IFN therapy is rare. Comparison of IFN alfa-2b eyedrops with surgical treatment of non-invasive squamous neoplasia has revealed a comparable cure rate (total resolution in 96.4% of patients).

with eyedrops producing better cosmetic results and less destruction of limbal stem cells. While we found no mention of this treatment in the dermatological literature, several ophthalmologic publications describe the effectiveness of topical IFN alpha-2b in cases of viral warts, intraepidermal carcinomas, and even melanomas on the eyelids and ocular surface, although these results are described in small series or isolated cases and should thus be interpreted with caution. We found no other cases in which IFN alpha-2b eyedrops have been used in the management of BCC of the eyelid. BCC is an accepted indication for IFN alpha-2b, and our findings point to a new potential route of administration. In our case the volume of the tumor decreased considerably, and the patient remains clinically stable after 3 years. However, we have no objective evidence of resolution, which requires close monitoring in a clinical setting. Our isolated experience should in no way change the standard accepted approaches used for the management of nonmelanoma skin cancer. Controlled clinical trials will be necessary to definitively determine the effectiveness of this treatment. However, given its ease of administration and its few, mild side effects, we propose the use of IFN alpha-2b eyedrops as a neoadjuvant therapy in selected cases to reduce tumor size before microscopically controlled surgical excision.

Aseptic and Alopecic Nodules of the Scalp†‡

Nódulos asépticos y alopecicos del cuero cabelludo

To the Editor:

Alopecic and aseptic nodules of the scalp (AANS), also known as pseudocyst of the scalp, is a new, little known, and probably underdiagnosed entity.

AANS was first described in the Japanese literature in 1992. The condition was described as pseudocyst of the scalp because histologic examination revealed cyst-like cavities lacking a true cystic wall. The first cases in Western populations were reported by Chevallier and coworkers in 1998, who described the lesions as non-infectious and alopecic scalp abscesses. In 2009, Abdennader and colleagues introduced the term “alopecic and aseptic nodules of the scalp”, as they failed to consistently find the cystic cavities described in the Japanese studies. About 70 cases have been described to date; these are listed in Table 1.

Case Description

We report the case of a 16 year-old male with an asymptomatic alopecic plaque on the right parietal region of the scalp. A soft, domed, erythematous, and slightly alopecic nodule of 3 cm in diameter surrounded by normal scalp was palpable on examination (Fig. 1). Biopsy showed an inflammatory lesion in the mid and deep dermis composed of granulation tissue, edema, reactive angioproliferation, and non-confluent granulomas, some with giant cells and others with central abscess formation (Fig. 2). Specific staining for microorganisms with Periodic acid Schiff (PAS), silver, Giemsa, and Ziehl-Neelsen was negative, as were mycological and bacteriological cultures. Treatment was initiated
