Dermoscopic Features of Sister Mary Joseph Nodule[☆]

Dermatoscopia del nódulo de la hermana María José

To the Editor:

Dermoscopy is a non-invasive diagnostic method that is used to evaluate morphological structures not visible to the human eye; dermoscopy thus helps us to differentiate and diagnose skin lesions.¹ It is a useful tool that has enabled us to perform rapid *in vivo* study.² There have been few publications on the use of dermoscopy for the diagnosis of skin metastases from malignant internal tumors.

We describe the case of a 67-year-old man who was seen for abdominal distension and an umbilical nodule that had appeared 6 months earlier. The patient reported constipation, abdominal pain, and weight loss of 5 kg in the previous month. On examination there was a firm, irregular, ulcerated erythematous nodule of 5 cm diameter at the umbilicus (Fig. 1A). The nodule contained serous fluid. Dermoscopy of the nodule with polarized light revealed white shiny structures and an atypical polymorphous vascular pattern with serpentine vessels and curved vessels with milky-red areas (Fig. 1B). This observation of polymorphous vessels and white shiny structures was suggestive of malignancy. Histopathology of the umbilical nodule revealed subcutaneous infiltration by a metastasis from an adenocarcinoma of the colon; the lesion was positive for cytokeratins CK7 and CK20 and CDX-2. Computed tomography and positron emission tomography showed a tumor mass at the hepatic angle of the colon, with liver, umbilical, and peritoneal metastases (Fig. 1C). Two liters of ascitic fluid were drained on paracentesis. Tumor resection was then considered, but the patient died before this could be performed.

Sister Mary Joseph's nodule (SMJN) is an eponym for umbilical skin metastasis from a malignant tumor. It is a rare manifestation, but may be the only presenting sign of a primary malignant visceral tumor.

The correct diagnosis of SMJN is crucial as it occurs predominantly in advanced or metastatic tumors. Clinically it presents as a small, irregular nodule that can be painful and can ulcerate; it can sometimes contain pus, blood, or serous fluid. The clinical differential diagnosis of SMJN includes malignant and benign lesions such as pyogenic granuloma, epidermal cyst, hemangioma, abscess, umbilical hernia, endometriosis, and primary umbilical carcinoma.³ Dermoscopic examination will exclude

pyogenic granuloma, basal cell carcinoma, and inflammatory conditions, as these would present other types of vessels.

To date, 3 reports have been published on the dermoscopic features of skin metastases from internal malignant tumors. De Giorgi et al.⁴ and Oiso et al.⁵ described atypical polymorphous vascular patterns in skin metastases from a recurrent thyroid carcinoma and in a skin metastasis from a possible occult breast cancer. But it was Mun et al.⁶ who first described the dermoscopic features of SMJN that had arisen from an adenocarcinoma of the pancreas. Recently, Chernoff et al.⁷ published an article in which they analyzed the vascular patterns of skin metastases; the most typical dermoscopic findings were serpentine vessels, linear irregular vessels, and unstructured homogeneous areas of pink color.

The dermoscopic vascular pattern is considered to be a pathognomonic phenomenon of neovascularization related to neoplastic growth.⁴ In the present case, dermoscopic examination of the umbilical lesion revealed a polymorphous vascular pattern that raised our suspicion of malignancy and led us to perform a skin biopsy that identified the presence of metastatic adenocarcinoma.

When an umbilical nodule is observed, a metastatic malignant tumor must be excluded as this may be its first clinical manifestation and indicates a poor prognosis. As far as we are aware, this is the second case report of the dermoscopic features of SMJN. The aim of this report is to increase the suspicion of a metastatic tumor when dermoscopic examination of an umbilical lesion reveals a polymorphous vascular pattern. Dermoscopy is now an essential additional tool for dermatologic diagnosis.

Schwannoma of the Tongue[☆]

Schwannoma de la lengua

To the Editor:

The schwannoma, neurilemmoma, or neurinoma is a benign tumor that arises from the Schwann cells of the cranial and peripheral nerves. It appears in individuals between 20 and 50 years of age and is equally common in men and women.¹

Schwannomas are usually sporadic, but in some cases they are associated with neurofibromatosis type II, schwannomatosis, Carney complex, or, more rarely, with radiation therapy, with a latency of up to 50 years (acoustic schwannomas).²

Around 25% of extracranial schwannomas arise on the head and neck, and approximately 1% are intraoral.^{3,4}

Our patient was an otherwise healthy man of 52 years of age, with no past medical history of interest. He presented a single tumor that had appeared 18 months earlier on the dorsum of tongue. The tumor was occasionally painful. There

was no history of surgery or trauma to the area. Physical examination revealed a nodule of 2 mm diameter on the dorsum of the tongue. The lesion was slightly erythematous, shiny, well-defined, slightly tender, and had a smooth surface and a rubbery consistency (Fig. 1).

Simple excision of the lesion was performed and histopathology revealed a clearly circumscribed tumor composed of fascicles of spindle-shaped cells, lying beneath the mucosa of the tongue (Fig. 2). At higher magnification, elongated cells were visible; the cells did not show atypia and their nuclei were arranged in line forming the typical "Verocay bodies" (Fig. 3). Immunohistochemistry was positive for S100. A diagnosis of classic schwannoma was made based on these findings.

After excision of the lesion, the wound was closed by direct suture and there have been no surgical complications or recurrence after 6 months of follow-up.

Schwannoma is rare on the tongue. Cohen et al.¹ performed a review of schwannomas on the tongue published in journals indexed in PubMed and found 126 cases over a period of 56 years (including 2 cases published in the same article).

Schwannoma presents clinically as a firm, slow-growing tumor that can reach a variable size. Symptoms depend on the site and size, and the tumor can be painful,³ as in the case we have presented, or asymptomatic. When situated on
